Supporting Information

ABSTRACT: Here we report carbon-based composites polyethylenimine-mesocarbon (PEI-CMK-3) and polyvinylamine-mesocarbon (PVA-CMK-3) that can be used to capture and rapidly release CO\textsubscript{2}. CO\textsubscript{2} uptake by the synthesized composites was determined using a gravimetric method at 30 °C and 1 atm; the 39% PEI-CMK-3 composite had ∼12 wt % CO\textsubscript{2} uptake capacity and the 37% PVA-CMK-3 composite had ∼13 wt % CO\textsubscript{2} uptake capacity. A desorption temperature of 75 °C was sufficient for regeneration. The CO\textsubscript{2} uptake was the same when using 10% CO\textsubscript{2} in a 90% CH\textsubscript{4}, C\textsubscript{2}H\textsubscript{6}, and C\textsubscript{3}H\textsubscript{8} mixture, underscoring this composite’s efficacy for CO\textsubscript{2} sequestration from natural gas.

KEYWORDS: CO\textsubscript{2} sequestration, mesoporous carbon (CMK-3), in situ polymerization, solid-supported amine sorbents, impregnation, polymer-carbon composites

INTRODUCTION

Since the industrial revolution, CO\textsubscript{2} emissions from fuel combustion have been growing rapidly. The increased CO\textsubscript{2} concentration in the atmosphere might contribute to apparent global warming and serious climate change. Reducing CO\textsubscript{2} emissions from industrial and natural gas streams therefore becomes an important issue. Furthermore, sequestration of CO\textsubscript{2} from atmospheric pressure environments is important in life-support systems in space and under water where compression is discouraged due to the energy penalty. Recently, CO\textsubscript{2} capture and sequestration have been receiving significant attention. Several chemical and physical methods were developed for CO\textsubscript{2} separation at near-atmospheric pressure. For instance, liquid sorbents made by aqueous amine species have been developed for commercial CO\textsubscript{2} separation. Even though aqueous amines have low cost and high efficacy, their regeneration requires high energy input. In keeping with the worldwide trend toward safer and cleaner processes, more environmentally friendly and less energy intensive solid sorbents are being developed to replace the conventional liquid sorbents. Activated carbon, one of the most common solid sorbents, is an extremely porous material that has been widely used as an industrial sorbent because of its high surface area and relatively high CO\textsubscript{2} capacity. Unfortunately, activated carbon has poorly controlled pore size distribution as well as a small pore volume, limiting its usefulness in CO\textsubscript{2} sorption. The grafting of amine functionalities onto a well-ordered solid support with a high surface area would combine the attractive features of the liquid sorbents with those of the solid sorbents. Accordingly, many types of amine-functionalized porous materials, such as M41S mesoporous silicas, have been used for CO\textsubscript{2} sequestration due to their high surface area and tunable pore sizes. Scaroni et al. invented “molecular basket” CO\textsubscript{2} adsorbents based on the solid sorbent MCM-41 modified with polyethylenimine; this material had a ∼3.0 mmol/g (~11.7 wt %) CO\textsubscript{2} capacity at 75 °C. Because the amine species were physisorbed on the support through impregnation rather than covalent modification, there is concern regarding the materials’ long-term stability over many reuse cycles since desorption of the amine functionalization might occur. Metal oxide frameworks (MOFs) are a class of sequestration materials that can reach 26% CO\textsubscript{2} uptake by weight at 25 °C and 1 atm, but their ability to sequester CO\textsubscript{2} in the presence of small hydrocarbons might be limited because of their poorer selectivity.

Over the last few decades, there have been significant advances in the synthesis of mesoporous carbon materials, such as CMK-3 and CMK-5. Ryoo et al. proposed a practical method through in situ polymerization to synthesize polymer-CMK-3 composites. The mesocarbon CMK-3 is different from conventional carbon materials such as activated carbon due to its highly ordered meso-structure and high surface area.

This allowed for the chemical properties of these composites to be maintained while greatly enhancing their thermal stability. Inspired by their work, we developed a route to synthesize polymer-mesocarbon composites that would lead to higher degrees of CO2 sorption by the in situ polymerization of amine species to produce polyethylenimine (PEI) and polyvinylamine (PVA) inside the mesocarbon CMK-3. In addition to a high efficiency for CO2 capture, they should also exhibit high stability due to the formation of interpenetrating composite frameworks between the entrapped polymers and mesocarbon CMK-3. Moreover, their uptake of small hydrocarbons should be minimal, making them suitable for use in CO2 sequestration from natural gas streams.

**RESULTS AND DISCUSSION**

Here, mesoporous silica SBA-15 synthesized by the surfactant-assisted method was used as a hard template to prepare mesoporous carbon CMK-3 as in the previous report. Scheme 1 demonstrates the synthesis route to the desired polymer-mesocarbon composites PEI-CMK-3 and PVA-CMK-3. For the synthesis of the PEI-CMK-3 composite, the as-synthesized CMK-3 was suspended in a solution containing 2-methyl-2-oxazoline monomers and acetonitrile. The monomers started filling the mesopores by capillary condensation, and the wall surface of the CMK-3 was coated with a thin film of monomers after evaporation of the acetonitrile at 80 °C. BF3·Et2O was used as a catalyst and was subsequently added for the polymerization step. A similar methodology was carried out for the PVA-CMK-3 synthesis except N-vinylformamide and 2,2’-azobis(2-methylpropionitrile) (AIBN) were used as the monomer and catalyst, respectively. The polymer-CMK-3 composites needed to be further hydrolyzed, thus becoming the PEI-CMK-3 and PVA-CMK-3 composites. More details are described in the experimental section.

Attenuated total reflectance infrared (ATR-IR) analysis and 13C NMR analysis were chosen to monitor the resultant composites during the synthetic processes. Figure 1a is the IR spectrum from CMK-3 impregnated with 2-methyl-2-oxazoline. The spectrum has a characteristic absorption band at 1673 cm⁻¹ that can be assigned to a symmetric stretching mode of 13C N vibration from the N-vinylformamide monomers and acetonitrile. The monomers started filling the mesopores by capillary condensation, and the wall surface of the CMK-3 was coated with a thin film of monomers after evaporation of the acetonitrile at 80 °C. BF3·Et2O was used as a catalyst and was subsequently added for the polymerization step. A similar methodology was carried out for the PVA-CMK-3 synthesis except N-vinylformamide and 2,2’-azobis(2-methylpropionitrile) (AIBN) were used as the monomer and catalyst, respectively. The polymer-CMK-3 composites needed to be further hydrolyzed, thus becoming the PEI-CMK-3 and PVA-CMK-3 composites. More details are described in the experimental section.

Attenuated total reflectance infrared (ATR-IR) analysis and 13C NMR analysis were chosen to monitor the resultant composites during the synthetic processes. Figure 1a is the IR spectrum from CMK-3 impregnated with 2-methyl-2-oxazoline. The spectrum has a characteristic absorption band at 1673 cm⁻¹ that can be assigned to a symmetric stretching mode of C=N from the 2-methyl-2-oxazoline. The presence of the N-substituted polyaziridine, generated from the ring-opening of 2-methyl-2-oxazoline, can be evidenced by a development of C=N vibration at 1632 cm⁻¹ as well as a disappearance of the original C=N vibration (Figure 1b).

Figure 1c is a spectrum of the composite after hydrolysis with aqueous NaOH for 12 h; the characteristic peaks of the N-substituted polyaziridine from Figure 1b are replaced by peaks at 3260 and 1605 cm⁻¹ that are assigned to N–H stretching and bending, respectively, from the secondary amine. In Figure 1d, a sharp peak together with a shoulder appear at 1636 and 1670 cm⁻¹, corresponding to the C==C and C==O symmetric stretching from the N-vinylformamide monomers in CMK-3. Figure 1e shows a strong peak centered at 1656 cm⁻¹ that is due to C=O stretching from the poly(N-vinylformamide) in the CMK-3 composite after the in situ polymerization. The structure of the PVA-CMK-3 composite was confirmed by the peaks around 3400 and 1605 cm⁻¹ in Figure 1f because of the N=H stretching and NH2 scissoring on the primary amine, respectively.

The molecular structures of PEI-CMK-3 and PVA-CMK-3 composites were further investigated by solid-state NMR analysis. 13C MAS NMR spectra were acquired using 1H–13C cross-polarization (CPMAS) with contact time of 1 ms. Figure 1g shows that the PEI-CMK-3 composite has two main signals observed at δ ~ 126 ppm and δ ~ 45 ppm corresponding to sp2-carbons from CMK-3 itself and to the –CH2– units of linear PEI, respectively. A minor shoulder around 165 ppm assigned to the carbamate is assumed to arise through the composite reaction with CO2 from the atmosphere during its storage. For the PVA-CMK-3 composite, the three carbon atom resonance peaks shown in Fig. 1h were assigned as follows: a sp2-carbon peak (δ ~ 130 ppm) from CMK-3 itself, a strong (δ ~ 46 ppm) and a medium resonance (δ ~ 38 ppm) attributed to the methine- and methylene moieties of the PVA main chain.

Transmission electron microscopy (TEM) and scanning electron microscopy (SEM) analyses were conducted to determine the morphologies and microstructures of the synthesized polymer-CMK-3 composites. A TEM image of the 39% PEI-CMK-3 parallel to the pore direction is shown in the Figure 2a. The small angle X-ray diffraction pattern (inset) clearly reveals the presence of hexagonally ordered porous structures for the produced polymer-CMK-3 composites. These ordered porous structures...
remain even after polymerization and hydrolysis. Images b and c in Figure 2 are SEM images taken of PEI-CMK-3 and PVA-CMK-3, respectively. Little bulk aggregation of polymer was observed on the outer surface, which means that the polymerization of PEI and PVA is primarily confined within the pores of the CMK-3. The resultant polymers form interpenetrating and inseparable composite frameworks with CMK-3, in good agreement with the high stability results obtained from the CO2 sorption cycle study.

The porous nature of the polymer-CMK-3 composites was further characterized by nitrogen adsorption isotherms, which allow calculation of specific surface area, pore volume and pore size distribution (see Table 1). Pure CMK-3 has a high surface area of 1350 m$^2$/g with its pore volume of 1.40 cm$^3$/g and pore diameter of 3.9 nm. The actual loading of each polymer in the CMK-3 was determined by thermogravimetric analysis (TGA). The PEI-CMK-3 and PVA-CMK-3 behave similarly as their loadings were almost 2-fold less than that of PEI-CMK-3 and PVA-CMK-3 composites. All of samples were pretreated at 100 °C under argon to remove moisture and other adsorbates. Once the chamber was cooled and temperature equilibrium (30 °C) was achieved, the gas flow in the TGA instrument was switched to CO2 so as to pass through the sorbents. The CO2 capacities of the sorbents with various amine species and loadings were measured at 30 °C and 1 atm and the results are summarized in Table 1. A capacity of 6.4 wt % (1.55 mmol/g) was obtained after feeding CO2 to the pure CMK-3 over 30 min. In the case of PEI-CMK-3 composites, the sorption quickly reached a plateau with CO2 uptake capacities between 8.1 and 12.1 wt % (3.13 mmol/g) as the PEI loading of the CMK-3 increased from 17 to 39 wt %. The capacities of the PVA-CMK-3 sorbents were improved from 10.3 to 13.4 wt % (3.52 mmol/g) with respect to similar PEI loadings. The ability of the PEI- and PVA-CMK-3 sorbents to capture CO2 could be related to the number of amine groups for reaction and the 2$^+$ vs. 1$^+$ amine difference in the two. In addition, the CO2 capacities for the PEI-CMK-3 (impregnated) and PVA-CMK-3 (impregnated) were almost 2-fold less than that of PEI-CMK-3 and PVA-CMK-3 sorbents made through the in situ polymerization method. The decreases in their CO2 capacities were likely due to plugging of the pores by polymer chains. Because mesoporous carbon CMK-3 has a hydrophobic framework, hydrophilic polymers might not easily infiltrate into the mesoporous channels of CMK-3, resulting in polymer agglomeration outside the CMK-3. Higher loadings of polymers (such as 52% PEI-CMK-3 and 54% PVA-CMK-3) likely blocked the mesoporous channels, causing CO2 diffusional limitations. These results are summarized in Table 1.

In addition to the high CO2 capture efficiency, long-term stability and low-cost regeneration are also important concerns for any CO2 sequestration system. In our case, as CO2 was introduced into the sorbents, each CO2 uptake cycle is a two-stage process, with the mass increasing significantly in the first stage in less than 5 min, followed by a second much slower sorption process until a stable maximum was reached (Figure 3). This two-stage sorption kinetics had been observed in other amine-impregnated sorbents. Note that the capacity of the 37% PVA-CMK-3 is higher than 13 wt % within the first CO2 exposure stage. The amine-based polymers are known to react with CO2 to produce carbamates through the formation of zwitterionic intermediates. The rapid sequestration process is desirable for shortening the CO2 sorption time. To check the stability of the composite sorbents, after the first sorption cycle, the cycling was repeated by heating the PEI-CMK-3 and

Sorption cycles of CO₂ studied by TGA at 30 °C on the 37% PVA-CMK-3 sorbent. The composite was first pretreated at 100 °C under argon to remove moisture and residual CO₂ followed by dosing with a 100% CO₂ gas stream (30 °C, 1 atm) for 30 min. After the first sorption cycle, the cycling was repeated by heating the adsorbent to 75 °C under argon for regeneration. The CO₂ uptake capacity was calculated based on the difference between the weight before and after CO₂ uptake using the raw data without further normalization.

PVA-CMK-3 composites to 75 °C under argon gas for regeneration, followed by cooling to room temperature for another CO₂ capture. The 75 °C regeneration temperature is lower than that needed for silica-based amine sorbents, which is typically higher than 100 °C.

It has been known that the CO₂ sorption by “molecular baskets” is very sensitive to temperature. The 37% PVA-CMK-3 sorbent was exposed to pure CO₂ at a temperature range from 30 to 75 °C. Clearly, as the temperature was increased, the composite reached a new sorption equilibrium. A plot of equilibrium CO₂ sorption versus temperature is given in Figure 1S. Furthermore, higher humidity improved the CO₂ capacity for amine-containing sorbents. Therefore we compared the CO₂ uptake efficiency for the PVA-CMK-3 sorbent under dry and moist conditions at 30 °C (see Figure 2S in the Supporting Information). Dry CO₂ was fed to the sorbent first and then the CO₂ was desorbed at 75 °C. After the weight of the composite was back to the original weight at 30 °C, the CO₂ was bubbled through a water container before being fed into the TGA chamber for sorbent uptake at 30 °C. No enhancement of CO₂ uptake was observed.

In addition to the 100% CO₂ flow, we used a 10% CO₂ in alkane mixture (composed of 85% CH₄, 3% C₂H₆, and 2% C₃H₈) in order to mimic a natural gas field. The result still showed ~12 wt % maximum CO₂ uptake capacity for PEI-CMK-3 and ~13 wt % for PVA-CMK-3 (Figure 4a, b). When CH₄ was used as the pure gas feed, only 1.5 wt % CH₄ capacity was observed (Figure 4c). Hence, there is selectivity between CO₂ and CH₄ gas.

In conclusion, we have synthesized new and efficient CO₂ sorbents based on amine-modified mesocarbon CMK-3 composites through in situ polymerization. The synthesis process results in the entrapped polymers interpenetrating the composite frameworks of the mesocarbon CMK-3. A CO₂ sorption capacity of 13.4 wt % (3.52 mmol/g) was obtained, which is more than twice that of the pure CMK-3. The sorbents are readily and fully regenerated at a relatively low temperature, they exhibit stability over repetitive sorption-desorption cycles, and there is CO₂ selectivity over alkane gases.
N-vinylformamide (0.30 g, 4.3 mmol) and 2,2′-azobis(2-methylpropionitrile) (AIBN, 0.03 g, 0.02 mmol) were mixed in THF (1.76 mL, 1.56 g, 21.7 mmol) and the mixture was stirred in a 20 mL sample vial for 6 h at room temperature. The vial was then heated in a 55 °C vacuum oven overnight. Additional portions of N-vinylformamide (0.30 g, 4.3 mmol) and 2,2′-azobis(2-methylpropionitrile) (AIBN, 0.03 g, 0.02 mmol) were added and the sealed vial was heated in a 90 °C oven for 12 h to produce a dark gray solid. The powder was transferred to a 250 mL round-bottom flask that contained 2 M aqueous NaOH (100 mL). The mixture was stirred and heated at 90 °C for 12 h. After cooling, the powder was recovered by filtration and the filter cake was washed with water until the filtrate was neutral to litmus paper. The product was dried in a vacuum oven at 80 °C overnight to yield 0.70 g of PVA-CMK-3.
